WILL THE REPUBLICANS RETAKE THE HOUSE IN 2010?

Alfred G. Cuzán

Historically, statistical models for forecasting the outcome of midterm elections to the United States House of Representatives have not been particularly successful (Jones and Cuzán 2006). However, in what may have been a breakthrough, in 2006 most models called it correctly (Cuzán 2007). However, in what may have been a breakthrough, most models correctly predicted that the Democrats would re-emerge as the majority party in 2006 (Cuzán 2007). One successful model was estimated using 46 elections, beginning with 1914 (only the second time that 435 representatives, the present number, were elected). The model was relatively simple, making use of national-level variables only (Cuzán and Bundrick 2006). Using a similar model, I generated a forecast for the 2010 midterm election.

The System to Be Modeled

As is well known, the party of the president, the incumbent, almost always incurs a net loss of House seats in midterm elections. More generally, across all congressional elections held since 1914, the in-party lost an average of 15 seats, more than offsetting the gains accompanying a presidential reelection. This is shown in Figure 1. Consequently, the incumbents always exit 1600 Pennsylvania Avenue with fewer House members than they elected at the beginning of their party reign (the entry election). In fact, in all cases but one they have concluded their reign with fewer seats than what they had won in the last midterm election held under the president of the other party (entry election minus one). For

example, the Republicans lost 56 seats between 1998, the last midterm election held under President Clinton, when they took 234 seats, and 2008, the exit election, when they were reduced to only 178 members. On average, it has cost a party 41 seats to have one of their own serve in the White House. The single exception to this regularity was the Reagan-G.H.W. Bush Republican reign, which netted the GOP 18 seats between 1978 and 1992. The Roosevelt-Truman Democrat reign, when the party lost only four seats between 1930 and 1952, came close to being a second exception. These patterns are displayed in Figure 2.

< Figures 1 and 2 about here >

Almost always, then, a party's tenure in the White House comes at the expense of the congressional wing of the party. However, since World War II the magnitude of the loss has ameliorated. This is also shown in Figure 2. In the first half of the 20th century, incumbents would incur a net loss of 100 or more seats from entry election minus one to the exit election. Between the 1930s and 1940s, both time series evidence "a time-trend slope change" (Duncan, Gorr, and Szczypula 2001, 198). Among post-war era reigns (i.e., since Eisenhower's), the average net seat reduction over a party's reign has amounted to 35 seats. The erosion of the incumbent's congressional representation, though inevitable, is now less pronounced than it once was. The system appears to have settled into a stable "pattern regime" (Duncan, Gorr, and Szczypula 2001, 198). Why that is the case is beyond the scope of this paper.

Turning to midterm elections, since 1914 the incumbents have lost an average of 30 seats, although there is a good deal of variation around that number (sd=26). As Figure 3 shows, in 14 elections, the incumbents lost no more than the

average; in six of those elections, the damage was limited to half that many; and in three elections, the incumbents actually gained seats, with exceptions occurring in 1934 (+9), 1998 (+5), and 2002 (+8). In most of the remaining 10 cases, the incumbent party's losses were greater than 40 seats, costing them control of the House four times (1930, 1946, 1954, and 1994).¹ If history represents actual odds, the ratio of one type of outcome to the other is 7 to 5. The big question for 2010 is: will the almost inevitable contraction in representation that the Democrats will experience in 2010 be contained, or will it be large, drastically reducing their majority or even causing Nancy Pelosi to surrender the Speaker's gavel to a Republican? To answer that question, I present an account of past outcomes with a general model. After assembling a set of causal or at least predictive factors, I take up the eponymous question.

< Figure 3 about here >

Model Building

A structural model of the number of seats won by the incumbents serves as the point of departure. This model is built in steps. First, the following simple equation is estimated:

$$\text{IncSeats} = A + \beta_1(\text{IncSeats}_{t-1}) + \beta_2(\text{Loss1932Win1948}) + \varepsilon$$

That is, the number of seats won by the president's party is calculated as a simple function of two variables. The first is the result of congressional elections lagged one two-year term. The second is a dummy variable for controlling two outliers, both of which fall in presidential election years. In the 1932 election, the Republicans lost 101 seats, the largest on record. By contrast, in 1948, the

Democrats netted 75 seats, by far the biggest gain in the series. To appreciate the exceptional nature of these outcomes, consider that the average change of seats is -16 ($SD = 33$) across all elections, and -2 ($SD = 34$) across presidential elections only. The second largest loss occurred in 1938 (-72) and the second largest gain in 1964 ($+36$). To control for those extraordinary elections, $Loss_{1932}Gain_{1948}$ takes the value of -1 in the earlier year, 1 in the latter year, and 0 in all other years. The results of estimating this model appear in the first column of table 1. Model 1 accounts for two-thirds of the variance in the dependent variable; its standard error is 27 seats. This simple model yields a naïve point forecast of 236 seats for the incumbents in this year's midterm election, producing a net loss of 21 seats.

<Table 1 about here>

Next, additional variables previously shown to have some effect on House elections (Jacobson 1985; Erikson, MacKuen, and Stimson 2002) are serially incorporated into the model. Model 2 adds two categorical variables. One is $PrezElect$. It indicates whether the incumbent party is returned to the White House in a presidential election year, scored 1 if the party is reelected, and -1 if it is defeated. (In a midterm election year, the variable takes the value of 0 .) The other variable is $Midterm$, marked 1 if it is a midterm election and 0 if it is a presidential election. Observe that winning another term in the White House on average yields 27 new members from the president's party. (Since the variable ranges from -1 to 1 , the coefficient has to be multiplied by two to compute its impact on seats.) This is called the "coattails effect" (Jacobson 1987, 150). On the other hand, a midterm election typically costs the incumbents about 23 seats. This model forecasts that the Democrats will win 225 seats, for a net loss of 32.

Next, in the referendum tradition pioneered by Kramer (1971), the annual growth in real GDP per capita and the yearly change in the consumer price index (CPI) are incorporated into Model 3. These variables exert contrasting effects of approximately the same magnitude. With every percent point increase, one adds while the other subtracts approximately two seats from the incumbent total. Inclusion of these variables shaves off more than one-third from the coefficient of PrezElect. This effect reflects the well-established correlation between economic performance and presidential reelection and supports Jacobson's observation that the coattail effects "are erratic and usually modest" (Jacobson 1987, 50). Model 3 accounts for over 80% of the variance in the dependent variable, with an SEE of 20 seats. Finally, the far-right column of table 1 displays a model estimated using midterm elections only (Model 4). Note that in this model, the effect of economic growth holds up fairly well, but the effect for inflation shrinks. Table 2 displays the performance of Model 3 in one-step-ahead forecasts, starting with the 1994 midterm election. The mean absolute error (MAE) of the forecasts is 14 seats, and the median absolute error (MdAE) is 11 seats. However, in three (1994, 1998, and 2002) of the eight cases, the absolute error was large. Two of those errors were incurred in atypical elections, when the incumbents gained rather than lost seats, and may be accounted for by extraordinary events—respectively, the backlash against the impeachment of President Clinton and the rallying effect of September 11. On the other hand, there is no obvious event that one can single out as a suspect in 1994, President Clinton's first midterm election, an electoral debacle for the Democrats that cost them control of both chambers of Congress for the first time in four decades.

<table 2 about here>

Forecast for 2010

For the purpose of generating a forecast for 2010, it is assumed that for this year, (1) real per capita GDP grows 2% and (2) inflation is limited to 1%. I arrived at these assumptions by surveying collections of economic forecasts (see, e.g., Pearson 2010 and Izzo 2010). The bottom row of table 1 displays the number of seats won by the Democrats that is obtained by injecting these economic inputs into Models 3 and 4. These numbers are 230 and 227, respectively, producing a loss of between 27 and 30 seats—about average for a midterm election. Since a loss of 40 seats is required for a party turnover, the Democrats are expected to retain their majority. The probability that they will do so is 0.73 with Model 3 and 0.66 with Model 4. Still, those probabilities mean that the chances of the GOP assuming control of the House are not trivial—between one in three and one in four. Also, recall that historically, 40% of midterm elections (10 out of 24 cases) have resulted in a loss by the incumbent party of 50 seats or more. In sum, although the model forecasts lean against it, a change in party control cannot be dismissed *tout court*.

Discussion

The foregoing analysis suggests that when it comes to the race for control of the House of Representatives, the Democrats have the edge. They stand to lose 11% to 12% of their representation, which is average for a midterm election ($M = 12\%$, $SD = 9$). That number would not be enough to dislodge Nancy Pelosi from the Speaker's chair. However, there is a nontrivial chance that 40 or more of their members will be defeated in November, an outcome that would reduce them to

minority status. To evaluate that possibility in historical perspective, two previous midterm elections, both the first of a new president, will serve as reference points, although neither ultimately involved a party turnover.

In 1982, the Republicans—who two years earlier had elected Ronald Reagan president without capturing the House—lost 26 seats, or 14% of their membership. The state of the economy was a salient issue at that time, as it is this year. Its effect is incorporated into Models 3 and 4. Indeed, the out-of-sample prediction for that year is 162 with Model 3 and 169 with Model 4, an error of -4 and +3, respectively (the actual value was 166 seats), or an absolute error of about 2% of the prediction. If the Democrats lose the same share of their membership this year as the Republicans did in 1982, their representation would shrink by 36 seats. This would amount to an absolute error of 3% with either Model 3 or Model 4.

The 1966 election provides another benchmark. That year, the economy experienced vigorous growth (5.3%), while inflation, although accelerating, was still somewhat contained (2.85%). Nevertheless, the Democrats lost 48 seats (16% of their membership). Other influences, which are not incorporated into any of the models in table 1, may well account for the beating that the Democrats took at the polls that year, including a backlash against the “Great Society” program.²

Unsurprisingly, then, in that election the out-of-sample predictions of both models overshot the mark. Whereas the Democrats won only 247 seats, Model 3 predicts 263 and Model 4, 259 seats. These predictions represent an error of 5-6%. Similarly, as may be gathered from surveys showing that a majority of respondents either disapprove of President Obama’s performance on health care

or favor repeal of the health care legislation enacted earlier this year,³ it appears that, on balance, the Democrats' progressive program is encountering a negative public reception. If their losses in percent terms match those of 1966, their numbers will be reduced to 216, two seats short of a majority. That would amount to an error of 14 seats with Model 3 and 11 seats with Model 4, about the same percent error as the out-of-sample prediction for 1966.

Summing up, according to the statistical analysis displayed in table 1, Models 3 and 4, the Democrats are forecast to lose 27 to 30 seats in November, staving off the Republican attempt to retake control. However, also according to those models, there is one chance in three or four that the Democrats will lose at least 40 seats, which would reduce them to minority status. In fact, the historical distribution of incumbent midterm losses displayed in figure 1 suggests that the odds of such an outcome occurring are around two in five. This should make the Democrats nervous—and stoke Republican hopes.

In conclusion, whether the House of Representatives undergoes a party turnover in November is contingent on some combination of random disturbances and systemic factors not included in any of the models in table 1, such as the aforementioned conservative reaction to liberal legislation, all of which are swept into the error term.⁴ Hence, the answer to this article's eponymous question is an emphatic "maybe."

Notes

* Many thanks to J. Scott Armstrong, Randall J. Jones, Jr., Ray Fair, and William B. Tankersley for their comments and suggestions on an earlier draft. Special thanks to Mike Bundrick for his help throughout. Needless to say, I bear sole responsibility for any errors.

1. In the 1930 election, the Republicans emerged with a one-seat majority. However, several members died before Congress convened the following year, and in the special elections called to replace these members, enough seats shifted to the Democrats to allow them to elevate one of their own to the speakership.

2. For a discussion of how public mood moves in the opposite ideological direction as that of legislation, as well as a list of important liberal laws enacted during the period, see Erikson, MacKuen, and Stimson (2002), Chapter 9.

3. See the rolling average at Pollster.com, RealClearPolitics.com, and RasmussenReports.com.

4. See an interesting discussion of “the lowly error term” in Erikson, MacKuen, and Stimson (2002), pp. 419–20.
